Usage-based AI exposure across Australia's earnings distribution

Summary of a working draft

Luc Taya, Economics (Honours) graduate, University of Western Australia

2026-10-26

Descriptive; not a job-loss or career-risk score; not advice.

The data behind this work are task-level Claude.ai and first-party API use by self-selected users of one provider, classified to US occupational tasks. No Australian occupational AI use is measured. The scores describe tasks in US occupations; this work applies them to the occupations Australians work in, and compares them with measures of what AI could do that do not come from Anthropic.

The question

How is measured AI use distributed across Australia's earnings distribution? And where does measured use rank occupations higher or lower than measures of what AI could do? Australian monitoring of generative AI has so far relied on measures of potential, such as Jobs and Skills Australia's exposure scores. Knowing which earners' occupations AI is actually used in comes before questions about wages, jobs or the tax base.

What was done

Anthropic's usage-based "observed exposure" scores (Massenkoff and McCrory, 2026) were linked from US occupations to the 358 ANZSCO unit groups used in ABS Labour Force data, through the US and international occupation classifications. Each unit's score is an employment-weighted average of the US occupations linked to it. Units were then ranked by ABS weekly earnings and grouped into ten employment-weighted deciles. Each unit's rank on usage was compared with its rank on Jobs and Skills Australia's automation and augmentation scores, Eloundou et al.'s measure of what language models could do, and Felten et al.'s AIOE.

The scores cover 99.1% of Australian employment. Every result is repeated under four ways of linking the classifications, three earnings rankings and five samples (60 specifications in all), and reported whether or not it holds.

What the figures show

All figures are for the main specification. The alternatives are in the note's appendix.

- **Concentration is robust.** Usage-based exposure is concentrated among higher earners (concentration index 0.09), and the index is positive in all 60 specifications.
- **The shape is not.** Exposure averages 0.07 in the bottom earnings decile, peaks at 0.19 in decile 7 and is 0.11 in the top. The bottom-to-top difference moves a lot when single large occupations are left out, and turns negative under one of the four ways of linking the classifications.
- **Any use, not heavier use.** Most of the difference is whether an occupation's tasks show any measured use at all: that share rises from 0.39 to 0.81. How heavily use shows up, once it does, is lower at the top than at the bottom.
- **Between two kinds of potential measure.** Compared on ranks, measured use is less concentrated among high earners than measures of what AI could assist with (JSA augmentation, Eloundou et al., AIOE) and more concentrated than JSA's automation scores.
- **Disagreements.** The largest disagreements with JSA's automation scores are mostly clerical, driving and hospitality-management occupations that measured use ranks well below JSA.
- **Women and men.** Women's average usage-based exposure (0.14) is above men's (0.10) in every earnings decile. This reflects the occupations they work in, not how individuals use AI.
- **Three checks added for v1.0.** Under simulated uncertainty in the crosswalk and in published earnings, the concentration among higher earners holds in every draw, but the peak in decile 7 holds in only 36%. Microsoft's Copilot-based measure of AI applicability, mapped the same way, is not concentrated among higher earners under

the main earnings ranking, so part of the pattern may be specific to Claude's users. And across occupations, measured use stops rising with earnings once you hold fixed whether the work can be done at home, a proxy for computer-based work.
- **Western Australia.** WA's average (0.107) is 11 per cent below the national one (0.120), entirely because of occupation mix, mostly its smaller share of professionals.

What this does not show

The usage data come from one provider's users, and the source classifies the task in each conversation, not the job of the person having it. Who uses a platform shapes what its logs show, and a Copilot-based comparison suggests part of the pattern is specific to Claude's users. Over half of the scored US occupations score zero, which means their tasks fell below a usage threshold or failed the capability gate, not that no one uses AI for them. Nothing here estimates whether AI changes employment, earnings or hours.

No funding. The analysis code was written with Claude Code, an AI coding assistant, under the author's direction, and Claude Code drafted parts of the text; the author wrote the revised framing and reviewed and approved all of it. Anthropic had no role in this work.
