Usage-based AI exposure across Australia's earnings distribution

Mapping US task-usage data onto ANZSCO occupations

Luc Taya, Economics (Honours) graduate, University of Western Australia

2026-10-26

> **Working draft v0.9, comments welcome.** Descriptive; not a job-loss or career-risk score; not advice.

The data behind this note are US task-level Claude.ai use by self-selected users, from one product. No Australian occupational AI use is measured. The usage-based exposure scores describe tasks in US occupations; this note applies them to the mix of occupations in Australian employment. Where the source data have Australian rows, those rows classify the task in a conversation, not the user's job. Every result is shown beside at least one measure that does not come from Anthropic.

1 Question and motivation

Question. How is measured AI use, as captured by usage-based exposure, distributed across Australia's earnings distribution? And where in that distribution does measured use run ahead of, or behind, measures of what AI could do?

Why it matters for Australia. Earlier waves of technical change reshaped the occupational structure in ways that mattered for earnings inequality in Australia [1]. Australian monitoring of generative AI so far rests on measures of potential. JSA's automation and augmentation scores rate what language models could do to each occupation's tasks [2], and DEWR's monitoring framework uses them to track employment [3]. e61 has argued that exposure metrics alone are a partial guide and that analysis should move beyond them [4]. The e61 revenue scenarios assume any AI wage change is spread evenly across the income distribution [5]. Where measured use actually sits in the earnings distribution is a prior question for both: which earners' occupations does AI touch now, rather than which it could touch?

What is new. Three pieces of work come closest:

- **DEWR (2026)** converts Massenkoff and McCrory's usage-based observed exposure to ANZSCO unit groups and uses it as an alternative measure in a model of employment. It does not examine earnings.
- **Demirev (2026)** maps an earlier Anthropic usage score to ANZSCO through three-digit ISCO, to study Australian job postings. It also does not examine earnings.
- **US work** compares usage with capability (Massenkoff and McCrory 2026; Tomlinson et al. 2025). The closest is Levkoff (2026), who reports that observed exposure rises with US wage quintiles. Levkoff also shows that its agreement with Eloundou et al.'s capability measure comes mostly from the measure's own capability gate.

This note adds four things:

1. the usage-potential gap across employment-weighted Australian earnings deciles, against two independent potential measures and one that is partly mechanical;
2. a split of usage-based exposure into an extensive margin (any measured use among linked US occupations) and intensity;
3. how Western Australia differs from the national picture through occupation mix alone, and results for women and men;

4. a crosswalk graded unit by unit and run under four weighting schemes, with every specification reported whether or not it holds.

Scope. The note moves from what AI *could* be used for to what it *is* being used for. It does not move to labour-market outcomes, and it makes no causal claims.

2 Data

Usage-based exposure. The measure is Massenkoff and McCrory's "observed exposure" [7], published as `job_exposure.csv` in the Anthropic Economic Index dataset [8]. It gives one score for each US occupation at the six-digit level of the SOC 2018 classification. The file has 756 rows. Of these, 411 (54%) are exactly zero; the mean is 0.077 and the maximum 0.745. Another 111 of the 867 detailed SOC occupations have no row, and these are treated as missing, not zero.

The score is built in steps, which matter for reading it:

- Each O*NET task is first gated on use. A task counts only if its work-related Claude.ai conversations plus all first-party API calls reach a fixed count in Anthropic's samples.
- It is then gated on capability: the task must have an Eloundou et al. beta above zero [9].
- Tasks that pass both gates are weighted between one half (augmentation only) and one (automation only).
- The job score is the time-share-weighted sum over the job's tasks.

So a zero means the job's tasks fell below the usage gate, or that none of its used tasks passed the capability gate. It does not mean no use at all. Zeros are flagged as "below usage threshold" wherever unit values are shown. The conversations are global Claude.ai and API traffic, classified into US O*NET tasks. Levkoff (2026) describes the usage as drawn from the Anthropic Economic Index releases up to November 2025.

Australian usage composition. For the comparison of usage with employment by occupation group (Section 4.6), the note uses the 2026-06-26 release of the AEI geography file. It covers Claude.ai conversations in 2 months, with 11,629 rows for Australia and 1,172 for Western Australia. For countries and subregions, detailed SOC rows are published only as shares of conversations. Collaboration measures, such as the automation share, exist for countries only at the SOC major-group level. Missing rows mean the cell was not published, not that it was zero.

Potential exposure. Three comparison measures do not depend on Claude.ai use:

- Jobs and Skills Australia's automation and augmentation exposure scores for ANZSCO unit groups [2], available for 357 unit groups;
- Eloundou et al.'s beta, rated by GPT-4, averaged from O*NET occupations to SOC codes [9];
- Felten, Raj and Seamans's AIOE [10]. The AIOE repository states no licence, so AIOE appears only in aggregate statistics and never for a single occupation.

Employment. Employment weights come from ABS Labour Force table EQ08 [11]. It gives employed persons by ANZSCO v1.2 unit group, sex and state each quarter. The weights average the 4 quarters from May 2025 to February 2026: 14.67 million people employed, 1.66 million of them in Western Australia. EQ08 was the final release under that title. ABS has said the table is not published from April 2026 [12], and Labour Force occupation data are coded to OSCA from the September 2026 reference period [13]. Neither source states whether unit-group detail will be published.

Earnings. Units are ranked by average weekly total cash earnings of all employees in the ABS Employee Earnings and Hours survey, May 2025 (data cube 11) [14]. No EEH cube gives hourly earnings at unit-group level. Two alternative rankings are reported in the appendix:

- average hourly total cash earnings of full-time non-managerial adult employees (EEH cube 13, published only for three-digit minor groups);
- average salary or wage income from ATO Taxation Statistics 2023-24, Table 15B [15].

EEH excludes owner-managers; EQ08 counts everyone employed.

Crosswalks. US occupations are linked to ANZSCO through BLS and ABS concordances: SOC 2018 to SOC 2010, SOC 2010 to ISCO-08, and ISCO-08 to ANZSCO v1.2. A fourth weighting scheme uses Jobs and Skills Australia's direct correspondence from ANZSCO v1.2 to O*NET-SOC 2019, an archived copy [16]. Within each unit, US occupations are weighted by employment in the BLS Occupational Employment and Wage Statistics for May 2025 [17].

Every file's source, access date, checksum and licence are recorded in `data/raw/MANIFEST.csv`.

3 Methods

Main specification. All results in the body of the note use one specification:

- weighting scheme 1 (US employment weights);
- all unit groups;
- EEH weekly earnings for the ranking;
- JSA automation as the primary comparator.

Each of these was fixed before any result was produced. Every alternative is in the appendix.

3.1 Edition spine

The analysis unit is the ANZSCO v1.2 unit group, because employment by sex and state is published only in that edition. There are 358 unit groups.

- **nfd codes.** Employment coded only to a broader group ("not further defined") is shared among the unit groups under it, in proportion to their employment in the same quarter, sex and state. These codes hold between 1.8% and 2.6% of employment in each quarter.
- **ANZSCO v1.3.** It has exactly the same codes as v1.2, so it needs no bridge.
- **ANZSCO 2021 and 2022.** EEH and ATO use these editions. They are brought back to v1.2 through the ABS correspondence tables. Of the 369 unit-to-unit links, 337 keep the same code, 5 are recoded, 14 merge several units into one, 7 split one unit across several and 6 are many-to-many.
- **Merges and splits.** A v1.2 unit fed by several newer units takes their mean, weighted by ATO individual counts. A newer unit split across several v1.2 units passes its value to each.
- **Missing earnings.** Units with no published EEH value after bridging (19 units) take the employment-weighted mean of their published siblings in the same minor group. Each one is listed in the appendix.

3.2 Usage-based exposure for each unit

The usage-based exposure of unit a is

$$e_a = \sum_{s \in S_a} w_{as}\, e_s, \qquad \sum_{s \in S_a} w_{as} = 1,$$

where S_a is the set of linked US occupations with a non-missing score, and the weights are renormalised over that set. The extensive margin applies the same weights to an indicator of any measured use, $\sum_s w_{as}\, \mathbf{1}[e_s > 0]$. Intensity is exposure divided by the extensive margin.

Four weighting schemes give four versions of every unit value:

1. **US employment weights** on the primary chain. This is the main scheme.
2. **Equal weights** on the same links.
3. **Title-match-first.** For each ANZSCO occupation, only US occupations whose titles match are kept if any match; otherwise all its links are kept. 150 occupations in 81 units have a match.
4. **The JSA correspondence links**, with US employment weights. They cover 354 units.

The primary chain gives 2,438 unit-to-occupation links through 429 ISCO-08 units. Because ISCO-08 is coarser than both SOC and ANZSCO, the chain smooths zeros into small positive values. Every unit is therefore graded by how many US occupations feed it:

Grade	Linked US occupations	Units	Share of employment
One-to-one	one	59	13.5%
Few-to-one	two to four	155	47.1%
Diffuse	five or more	141	38.5%

Each unit also carries the share of its linked US employment that has no score. When that share is high, the unit's value rests on a minority of its US counterparts.

A second chain, through the ANZSCO 2022 correspondence to ISCO-08, gives identical links for 350 units and different links for 8. Coverage is the share of employment in units with at least one scored US occupation. It is 99.1%, against a target of 98% set in advance.

3.3 Earnings deciles and concentration

- **Deciles.** Units are ranked by earnings and cut into employment-weighted deciles, so each decile holds a tenth of employment. A unit whose employment straddles a boundary is split between deciles in proportion. Decile means are employment-weighted. Decile intensity is mean exposure divided by mean extensive margin.
- **Top minus bottom.** The difference between the top and bottom deciles is reported in percentage points, never as a ratio.
- **Concentration index.** $CI = 2\,\mathrm{cov}(e, r)/\bar{e}$, with employment weights, where r is the employment-weighted fractional earnings rank. A positive index means exposure is concentrated among higher earners. It is not reported for AIOE, which is a standardised score with negative values.

3.4 Usage against potential

For each unit, the usage-potential gap is the percentile rank of usage-based exposure minus the percentile rank of the potential measure.

- Ranks are employment-weighted, and tied values share the mid-rank. In particular, every unit with zero usage-based exposure shares one rank.
- Unit gaps are averaged within deciles, with employment weights.
- The comparison with Eloundou beta is partly mechanical, because usage-based exposure is itself gated on that beta [6]. It compares use with feasibility inside the same task frame. JSA's scores and AIOE are the independent checks.

3.5 Women and men, Western Australia, and usage by occupation group

- **Women and men.** Deciles come from the persons earnings ranking. Within each decile, exposure is averaged with each sex's employment.
- **Western Australia.** The difference between WA and national mean exposure is

$$\Delta = \sum_{a} (s_a^{WA} - s_a^{AUS})\, e_a,$$

  where s are employment shares. By construction it reflects occupation mix only, since every unit carries one national value. Sub-major groups with fewer than five thousand WA workers are not shown separately, and no WA by sex results are produced.
- **Usage by occupation group.** Each SOC major group's share of Claude.ai conversations is divided by its share of employment.
  - For Australia and WA, employment is EQ08 allocated to SOC groups with the scheme 1 weights.
  - For the global row, it is US OEWS employment, because no global employment by SOC exists.

3.6 What counts as holding

These rules were fixed before any results were produced.

- **Decile profiles.** A profile holds under a variant if its OLS slope across deciles has the same sign as the main profile, and the Spearman correlation of the two sets of decile means is at least 0.7.
- **The gap.** The gap holds if its sign in the top and bottom quintiles is the same under every weighting scheme.

4 Results

4.1 The usage-potential gap by earnings decile

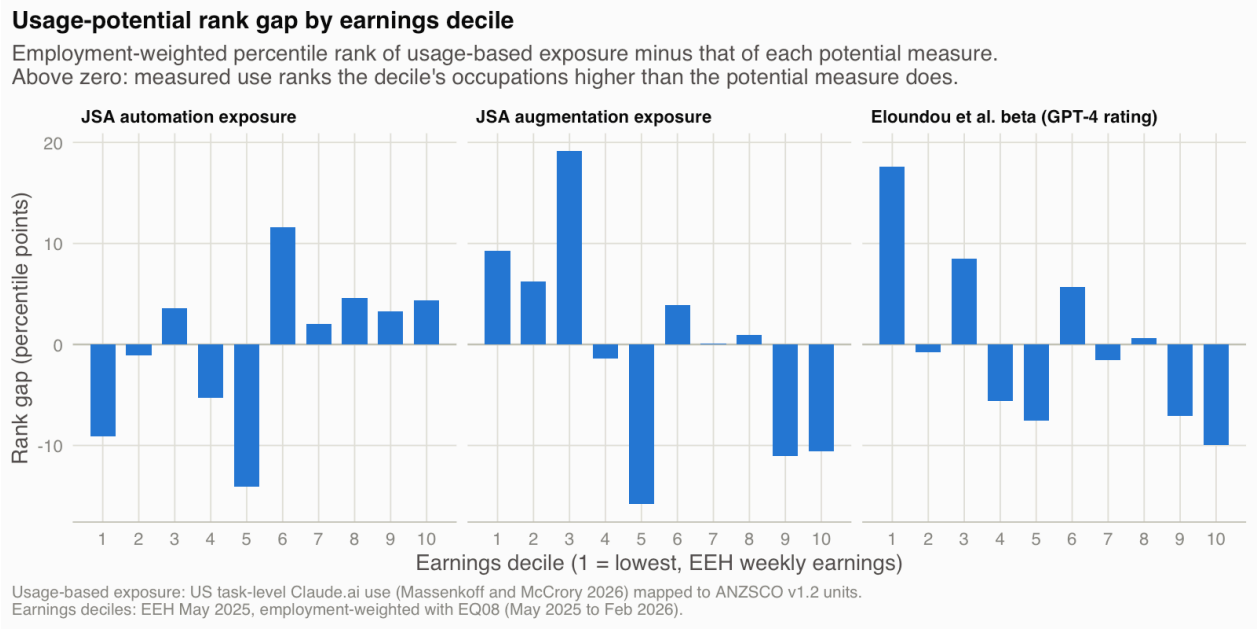

Figure 1: Employment-weighted percentile rank of usage-based exposure minus that of each potential measure, averaged within earnings deciles (main specification).

Against JSA's augmentation scores and Eloundou beta, usage-based exposure ranks the bottom earnings quintile higher (by 7.7 and 8.4 percentile points) and the top quintile lower (by 10.8 and 8.5). Against JSA's automation scores the signs reverse (−5.1 at the bottom, +3.8 at the top). The first two patterns keep their sign at both ends under all four weighting schemes. The bottom-quintile sign against JSA automation does not: scheme 4 gives +1.6.

4.2 Extensive margin and intensity

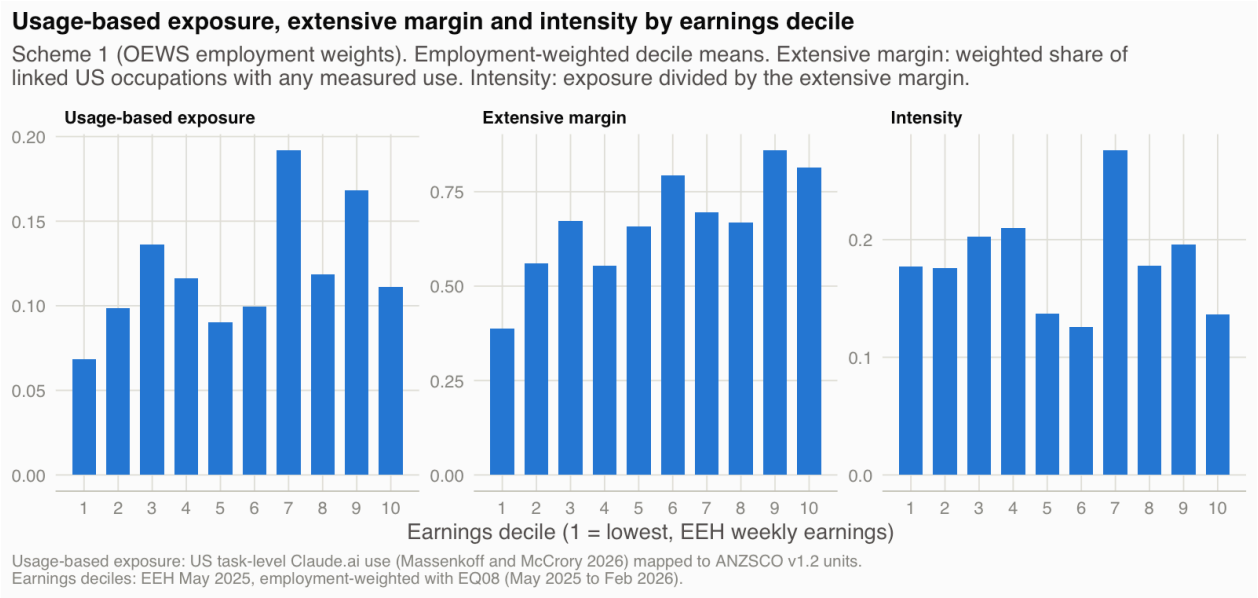

Figure 2: Usage-based exposure, extensive margin and intensity by earnings decile, main specification.

Mean usage-based exposure is 0.069 in the bottom decile and 0.111 in the top, a difference of +4.3 pp. The profile is not monotonic: it peaks at 0.192 in decile 7. The extensive margin rises from 0.39 to 0.81, while intensity stays between 0.13 and 0.28 with no trend. Across deciles, differences in usage-based exposure follow whether linked tasks show any measured use more closely than how heavily they are used.

4.3 Concentration

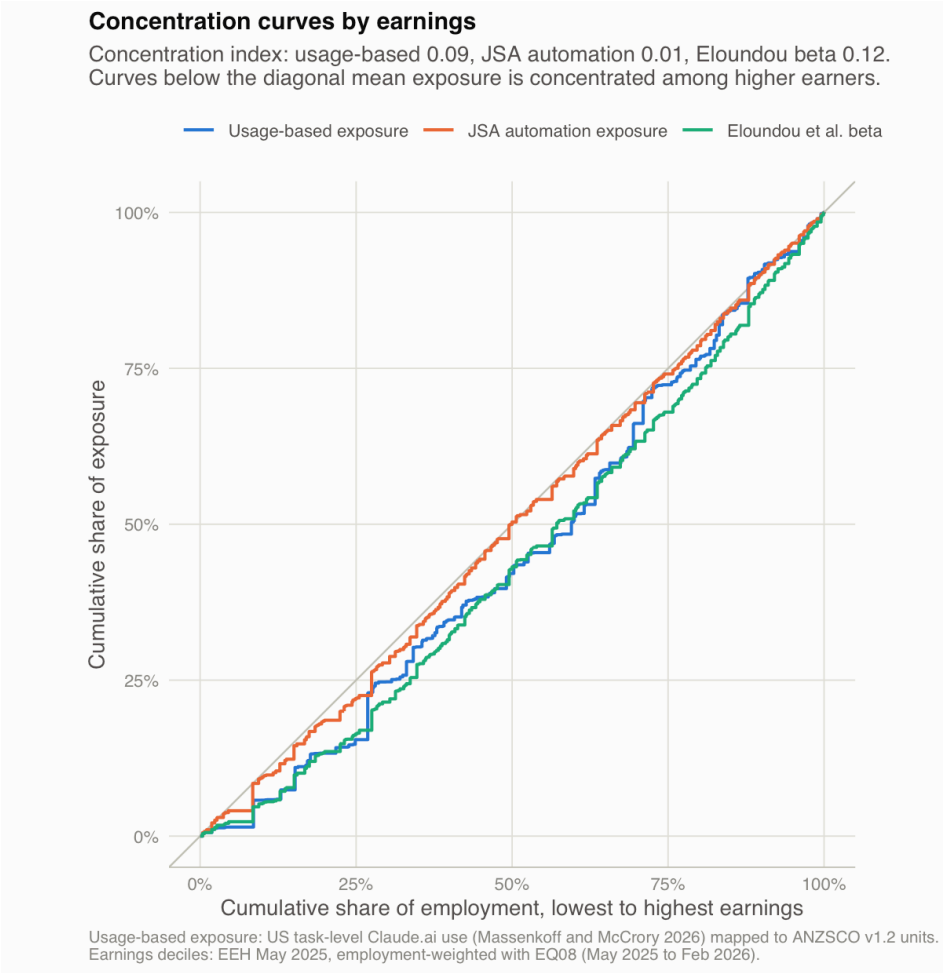

Figure 3: Concentration curves of usage-based exposure, JSA automation exposure and Eloundou beta, with units ordered from lowest to highest earnings.

Usage-based exposure is concentrated among higher earners: its concentration index is 0.089. That is less than Eloundou beta (0.116) but more than JSA automation (0.013) or JSA augmentation (0.037). Because the index summarises the whole distribution, it depends less on single deciles than the top-minus-bottom difference does.

4.4 Where usage and JSA disagree

Figure 4: Employment-weighted percentile ranks of usage-based exposure against JSA automation exposure, one point per unit group. Labelled points are the largest disagreements whose sign holds under every weighting scheme.

Across units, usage-based exposure and JSA automation are positively rank-correlated (0.72, employment-weighted). Of the 15 largest disagreements whose sign holds under every scheme, 12 are units that usage ranks below JSA, mostly clerical, driving and hospitality-management occupations. The units ranked above JSA are photographers, visual artists and electrical distribution trades workers.

4.5 Women and men, and Western Australia

Figure 5: Usage-based exposure of women and men by earnings decile.

Women's employment-weighted usage-based exposure (0.142) is above men's (0.100) overall and in all 10 deciles. By construction this reflects the occupations women and men work in, not differences within occupations. JSA automation shows the same direction (0.404 and 0.346).

Figure 6: Contribution of each occupation major group to the difference between WA and national mean usage-based exposure.

WA's mean usage-based exposure is 0.107, against 0.120 nationally. That difference of −1.4 (×100) reflects occupation mix only. Professionals contribute −0.96 of it: they are 25.2% of WA employment, against 27.8% nationally. JSA automation and Eloundou beta show WA differences of the same sign (−1.2 and −1.6).

4.6 Usage relative to employment by occupation group

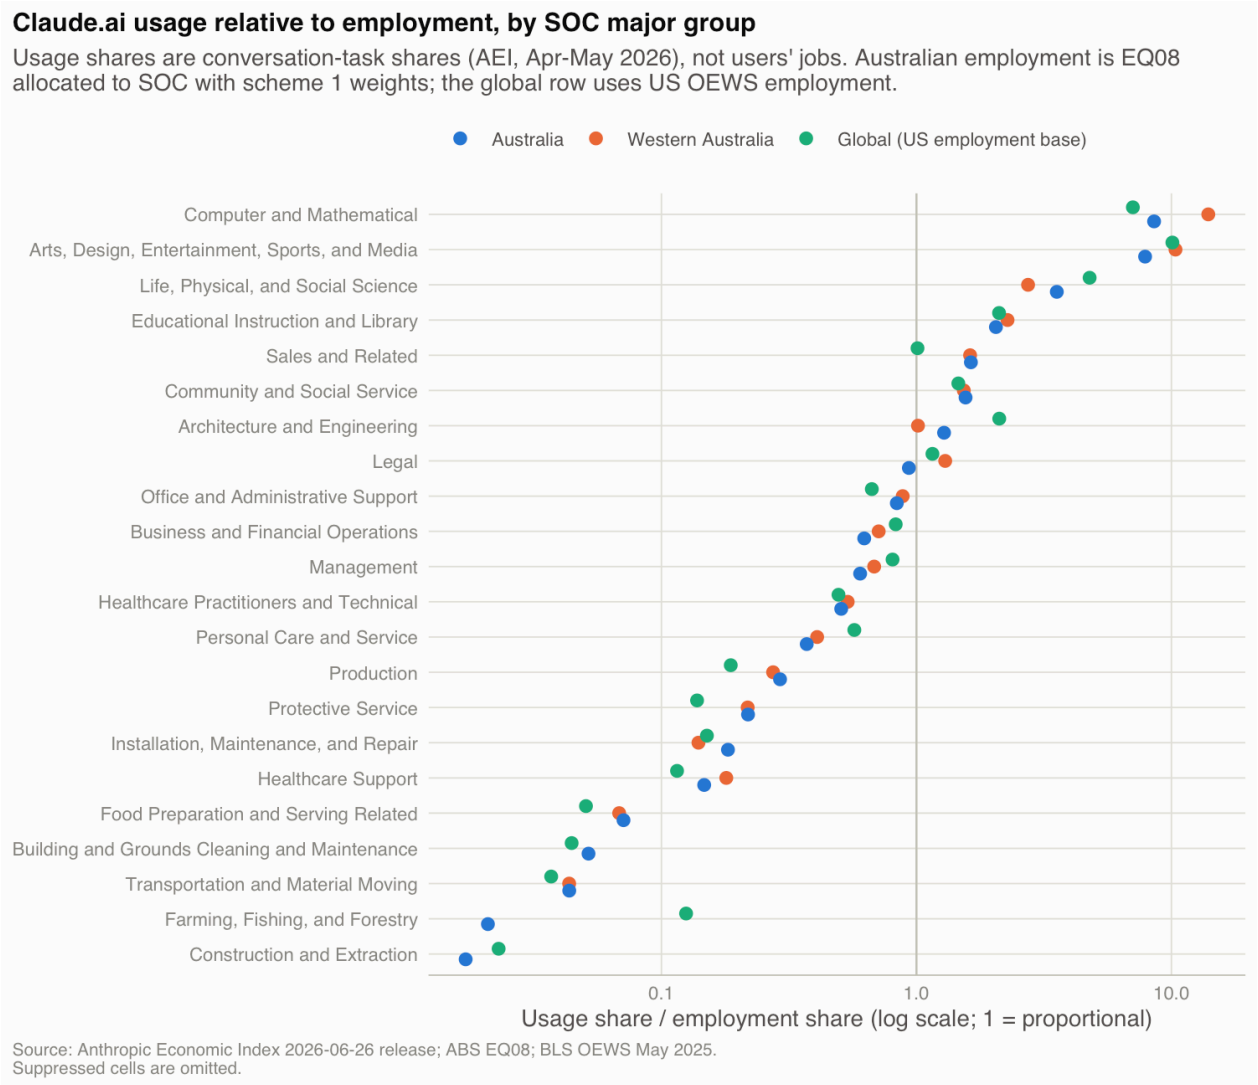

Figure 7: Claude.ai conversation share divided by employment share for each SOC major group, for Australia, Western Australia and the global sample.

Relative to employment, Australian Claude.ai conversations are most concentrated in Computer and Mathematical tasks (8.5 times their employment share) and least in Construction and Extraction tasks (0.02). 7 of 22 major groups take more than their employment share. WA's index for Computer and Mathematical tasks (13.9) is above Australia's and the global sample's (7.1). These shares classify conversation tasks rather than users' jobs, and WA's cells are small.

5 Robustness

32 of 60 specifications reproduce the main decile profile under the rule above. The appendix has every one: four schemes, three earnings rankings and five samples.

- **Steeper.** The non-diffuse units give a steeper gradient (+9.6 pp).
- **Similar to the main result:**
  - excluding units whose US counterparts are mostly unscored (+4.4 pp);
  - excluding units with imprecise earnings estimates (+4.2 pp);
  - excluding the draft list of owner-operator units (+3.2 pp).
- **Other earnings rankings:**
  - The hourly ranking gives a flatter gradient (+1.6 pp).
  - The ATO ranking gives a steeper one (+8.8 pp), but its decile profile does not hold (Spearman 0.62 with the main profile).
- **Scheme 4** reproduces the main profile in only 2 of 15 runs, because of one unit. Sales Assistants (General) holds 3.9% of employment, most of it in the bottom decile. Under that scheme it links only to US Retail Salespersons, a

known artefact of the source scores. Leaving it out moves the scheme 4 top-minus-bottom difference from −2.4 pp to +7.7 pp.

This influence check, and the exclusion of mostly unscored units, were added after the first results were seen. They are reported as such.

6 A framework for reading the results: AI in a two-capital model of the skill premium

This section extends the model in Section 3 of the author's honours thesis [18]. That model builds on the capital-skill complementarity framework of Krusell et al. (2000). The extension below, its derivations and their checks were drafted for this note; the thesis is unchanged. Every result is verified symbolically and numerically in `theory/check_theory.py` (output in `theory/check_theory_output.txt`).

Model (thesis notation). Output is a two-branch nested CES. Machinery K^M is paired with unskilled labour and ICT K^I with skilled labour:

$$Y = [\omega V^{\rho} + (1-\omega)X^{\rho}]^{1/\rho},$$

$$V = \left[\lambda U^{\eta_V} + (1-\lambda)(K^M)^{\eta_V}\right]^{1/\eta_V}, \qquad X = \left[\mu S^{\eta_X} + (1-\mu)(K^I)^{\eta_X}\right]^{1/\eta_X},$$

with $U = A^U N^U$, $S = A^S N^S$ and elasticities $\sigma_{VX} = 1/(1-\rho)$, $\sigma_{VU} = 1/(1-\eta_V)$ and $\sigma_{XS} = 1/(1-\eta_X)$. With competitive wages, the skill premium is

$$\pi = c_\pi \left(\frac{V}{X}\right)^{1/\sigma_{VX}} \left(\frac{X}{S}\right)^{1/\sigma_{XS}} \left(\frac{U}{V}\right)^{1/\sigma_{VU}} \frac{A^S}{A^U}.$$

Let $s_I = (1-\mu)(K^I)^{\eta_X}/X^{\eta_X}$ be ICT's cost share in the skilled branch and $s_S = 1 - s_I$; define s_M and $s_U = 1 - s_M$ likewise in the unskilled branch.

Lemma (benchmark). Holding technology fixed,

$$\frac{\partial \ln \pi}{\partial \ln K^I} = s_I\left(\frac{1}{\sigma_{XS}} - \frac{1}{\sigma_{VX}}\right), \qquad \frac{\partial \ln \pi}{\partial \ln K^M} = s_M\left(\frac{1}{\sigma_{VX}} - \frac{1}{\sigma_{VU}}\right).$$

These are the thesis's structural coefficients on ICT and machinery, evaluated at the current point. The author reports production elasticities, after removing induced technology, of $\sigma_{VX} = 2.21$, $\sigma_{XS} = 0.94$ and $\sigma_{VU} = 1.56$. The bracketed terms are then +0.61 and −0.19: ICT is a relative complement of skilled labour and machinery of unskilled labour. The thesis reports that a one standard deviation rise in ICT per skilled hour goes with a 12.5% higher premium, and the same rise in machinery with a 2.8% lower one.

Adding AI. Assumptions:

- (A1) AI capital K^A is an additional input. Technologies and the other inputs are held fixed, so the results are comparative statics, not dynamics.
- (A2) Factor markets are competitive, as in the thesis.
- (A3) AI enters in one of two ways.
  - **Scenario C, skill-complementing capital:** AI is ICT-type capital, $K^I \to K^I + \zeta K^A$ with $\zeta > 0$.
  - **Scenario D, skilled-task substitute:** AI performs skilled tasks, $S \to A^S N^S + \psi K^A$ with $\psi > 0$.
- (A4) Nothing here is estimated: ζ, ψ and the AI capital stock are unobserved.

Proposition 1 (scenario C).

$$\frac{\partial \ln \pi}{\partial \ln K^A} = \frac{\zeta K^A}{K^I + \zeta K^A}\, s_I\left(\frac{1}{\sigma_{XS}} - \frac{1}{\sigma_{VX}}\right).$$

This is positive if and only if $\sigma_{XS} < \sigma_{VX}$, the same condition as for ICT, which the thesis's estimates satisfy. Under the thesis's directed-technical-change condition the planner takes capital as given, so the response is scaled by $\phi/(\phi-1) > 1$ and its sign is unchanged.

Proposition 2 (scenario D).

$$\frac{\partial \ln \pi}{\partial \ln K^A} = -\frac{\psi K^A}{S}\left(\frac{s_S}{\sigma_{VX}} + \frac{1 - s_S}{\sigma_{XS}}\right) < 0$$

for all admissible parameters. The bracket is a weighted average of $1/\sigma_{VX}$ and $1/\sigma_{XS}$; with the thesis's elasticities it lies between 0.45 and 1.06. Because AI here enters the skilled efficiency unit itself, the planner's problem changes. The technology response is not derived, so this result is stated for given technology only.

Proposition 3 (both channels). If AI enters both ways, the response of $\ln \pi$ is the sum of the responses in Proposition 1 and Proposition 2. Its sign depends on ζ, ψ and the branch shares.

Remark. If AI instead performs unskilled tasks ($U \to A^U N^U + \psi K^A$), then $\partial \ln \pi / \partial \ln K^A = (\psi K^A / U)[s_U/\sigma_{VX} + (1 - s_U)/\sigma_{VU}] > 0$.

What the descriptive evidence can and cannot speak to. The model's skilled and unskilled labour are not observed here; the note has occupations and earnings, not education. Read loosely, with higher-earning occupations as the skilled branch, the results bear on *where* AI is used.

- **What it can speak to:** under both scenarios C and D, AI's use is located in the skilled branch. The rising extensive margin and the positive concentration index fit that location, and fit the remark's unskilled-task channel less well as a description of current use.
- **What it cannot speak to:**
  - It cannot tell scenario C from scenario D: both place use in the same occupations.
  - The AEI's automation and augmentation labels describe conversation patterns, not substitution in production.
  - Nothing here observes AI capital, its price, wages or elasticities, so the sign of Proposition 3 is not determined by these data.

The evidence restricts where AI is used. It does not tell us what AI does to the skill premium.

7 Limitations

One product and its users. Claude.ai and Anthropic's API serve a self-selected group of users. JSA reports that Claude.ai has under three per cent of Australian market share [2, pp. 35-36]. Usage-based scores built from one platform mix how applicable AI is to a task with who uses that platform [20]. Nothing in the note measures how Australian workers in a given occupation use AI.

Tasks, not jobs. The source classifies the task in each conversation, not the job of the person having it. The Australian rows used in Section 4.6 carry the same caveat.

Zeros, gates and stability.

- Over half of the scored US occupations have a score of exactly zero. A zero can mean the tasks fell below the usage gate in Anthropic's sample, or that the used tasks failed the capability gate.
- The gate also makes the comparison with Eloundou beta partly mechanical. Levkoff (2026) finds that most of the agreement between the two comes from the gate.
- Levkoff also finds that detailed occupation rankings change between Anthropic data vintages, while broad group structure is stable. Unit-level values in the explorer should be read with that in mind.
- Rebuilding the published scores from the published task data, with O*NET task weights in place of unpublished time shares, gives a rank correlation of 0.87 (appendix).

Known artefacts. Some scores sit oddly beside related occupations:

US occupation	Score	Related occupation	Score
Legal Secretaries and Administrative Assistants	zero	Paralegals and Legal Assistants	positive
Bartenders	zero		
Retail Salespersons	higher	Lawyers	lower

These pass through the crosswalk unchanged. Retail Salespersons carries much of the weight of Sales Assistants (General), the single most influential unit.

Crosswalk.

- The primary chain passes through ISCO-08, which is coarser than either end. Units fed by five or more US occupations hold 38.5% of employment.
- The ABS correspondence includes partial matches. These can attach small weights to US occupations that look unrelated, such as beauty and teller occupations for general sales assistants.
- 25 units, holding 5.9% of employment, have most of their linked US employment without a score. Aged and Disabled Carers is one: its main US counterparts have no score.

All of these are reported in the appendix, and the main results are rerun without them.

Earnings.

- Weekly earnings mix hourly pay with hours worked. No hourly earnings are published at unit-group level.
- EEH leaves out owner-managers, while EQ08 counts them. The owner-operator exclusion uses a judgement list, because ABS publishes form of employment only by major group [21].
- 19 units have no published EEH value and take their minor group's mean. 25 units have relative standard errors above 25%.
- In the ATO data, 23.1% of individuals have a blank or unclassifiable occupation code.

Sampling error. EQ08 publishes no standard errors. Unit-level employment, especially for Western Australia, is estimated with error that this note cannot show.

Timing. The four sources cover different periods:

Source	Period
Usage-based scores	Anthropic samples up to November 2025
Australian usage shares	April and May 2026
Employment	May 2025 to February 2026
Earnings	May 2025 (EEH) and 2023-24 (ATO)

Occupation-group shares. The published SOC major-group shares do not sum to one hundred per cent for any geography, even where all groups are published. The data documentation does not say what fills the gap.

Theoretical framework. It is a way of reading the results, not a test. It holds technology fixed except where stated, and maps skill to earnings only loosely.

What the note does not do. It describes; it does not estimate effects. It says nothing about employment, wages or hours responding to AI. It measures variation between occupations, not within them. It is not a forecast and not a job-loss or career-risk score.

8 What did not work, and changes along the way

- **The questions file.** A separate file of research questions and choices was dropped on 25 October 2026. The method choices it would have held were logged in `decision_log.md` before any results were produced. The research question, framing, takeaways and theory box were written after the first results.
- **Hourly earnings.** These were the intended primary ranking but are not published at unit-group level.
- **Owner-managers.** No unit-level data on owner-managers exist in published ABS tables, so that run uses a judgement list.
- **The concentration index for AIOE** was dropped, for the reason given in Section 3.
- **The JSA correspondence** turned out to be coded to ANZSCO v1.2, not v1.3 as its archived web page implied.
- **Weighting scheme 4** does not reproduce the main decile profile, and **the JSA automation gap** does not keep its sign in the bottom quintile across schemes.
- **Rebuilding the usage-based score** from task data fell short of its target (rank correlation 0.87 against 0.9).
- **Added after the first results:** the influence check, the measure of unscored US counterparts, and the sensitivity run built on it. All three are labelled where they appear.
